Abstract The discharge data of 80 stations (1981–2002) located in the Amazon basin are analysed in relation to the SST in the tropical Pacific and Atlantic oceans, using composite analysis. A wavelet analysis is performed on the 100-year discharge series at Obidos (downstream Amazon). Discharge is lower than normal during El Niño except in the western rivers (Solimões, upper Negro, and Japura) and in the southernmost regions (upper Madeira, Tapajós and Xingu basins). During La Niña, discharge is higher than normal in the north-eastern basin and, in contrast, lower than normal in the Madeira basin. However, the ENSO signal is not stationary at Obidos during the 20th century, when considering high flow and mean discharge. High discharges in a vast central region of the Amazon basin are associated with cold SST over the Northern Tropical Atlantic (NATL) during the low-flow season. Furthermore, a common, though not permanent, near-decadal signal is observed in Obidos low flow and NATL SST. The discharge of the southernmost Amazonian rivers is related to the south Atlantic SST; however, these signals are space and time dependent.

Key words Amazon Basin; Atlantic; discharge; ENSO; interannual variability; pluri-decadal variability; sea-surface temperatures (SST)

INTRODUCTION

The aim of this paper is to analyse the space–time variability of the relationships between the discharge within the Amazon basin and Atlantic and Pacific climatic indicators. Former studies realized by Molion & Moraes (1987), Richey *et al.* (1989), Marengo (1992, 1995), Amarasekera *et al.* (1997), Marengo & Tomasella (1998), Guyot *et al.* (1998), Uvo *et al.* (2000), Foley *et al.* (2002), using small data sets, generally coincide in finding lower (higher) discharge during El Niño (La Niña) in particular in the northern Amazon basin. Marengo (1992), Molinier *et al.* (2004), and Labat *et al.* (2004) also identified positive discharge anomalies when the Northern Tropical Atlantic is colder than usual. Recently, relationships between SST, discharge and inundations in the Mamoré basin and in the Madeira, Tapajós and Xingu basins

were described by Ronchail *et al.* (2003, 2004). The climatic signals in the southern tributaries of the Amazon basin are found to be time and space dependent.

Here we propose a new comprehensive analysis of the discharge–sea surface temperature (SST) relationships in the Amazon basin using the HyBAM (Hydrology and Geodynamics of the Amazonian basin) programme discharge data set, that is to say the daily discharge data of 80 stations (1981–2002) and the 100 years Óbidos rebuilt series (Callède *et al.*, 2002). Both classic statistical methods and wavelet analysis are introduced.

DATA AND METHODS

During the last two decades, within the framework of PHICAB (Climatological and Hydrological Program of the Bolivian Amazonian basin) and HyBAM (Hydrology and Geodynamics of the Amazonian basin) programmes coordinated by the IRD, a partnership was signed between this Institute and the SENAMHI (National Service of Meteorology and Hydrology, Bolivia), the SEMENA (Service for the Improvement of Amazonian Navigation, Bolivia) and the ANA (National Agency for Water, Brazil) in order to complement the hydrological networks. The daily water level data were corrected when necessary, eventually complemented using their correlation with data of upstream or downstream stations. The rating curves have been determined using the stream gauging measures (recently with ADCP) and have been used to convert the water levels series in discharge data.

The data of 80 stations was compiled (Fig. 1). The daily discharge data permitted the calculation of various hydrological variables during the 1981–2002 period:

- (a) The mean annual discharge computed for various hydrological years as various hydrological regimes are observed within the basin (Molinier *et al.*, 1996): October–September for the southern basins (Madeira, Tapajós, Xingu, Purus, Juruá, and Solimões), April–March for the Negro, the Branco and the Juruena basins and January–December for the northeastern tributaries.
- (b) The annual high flow (maximum) and low flow (minimum) discharge are also computed for the hydrological year. The minimum annual discharge that is retained follows the annual maximum, even though it occurs after the end of the hydrological year.

The sea surface temperature (SST) data set is from the Climatic Prediction Centre-NOAA. Monthly SST (1950–2002) were collected for Niño 1-2 (0°–10°S; 90–80°W), Niño 3 (5°S–5°N; 150–90°W), Niño 3-4 (5°S–5°N; 170–120°W), Niño 4 (5°S–5°N; 160°E–150°W), the Northern Tropical Atlantic-NATL (5–20°N; 60–30°W) and the Southern Tropical Atlantic-SATL (0–20°S; 30°W–10°E).

The Southern Oscillation Index (SOI), standardized difference of pressure between Tahiti and Darwin, and the Multivariate ENSO index (MEI—Wolter 1987) that synthesizes atmospheric and oceanic data in the equatorial Pacific are from the CDC-NOAA. The global SST data are from the NCEP-NCAR Reanalysis (Kalnay *et al.*, 1996). They are used to construct SST indices in various latitude-longitude boxes in the southwestern subtropical Atlantic. The results presented in this work are those with the averaged SSTs in a 20–30° south, 30–50° west box.

Fig. 1 Location of the gauging stations. Grey shading indicates regions above 500 m.

Composites and correlation analysis are used to measure the relationships between SSTs and discharge. Correlations are taken into account when they are significant at the 95% level. Discharge anomalies are taken into account when they are significant at the 0.90% level for a two-tailed test of the null hypothesis of no difference from the 1981–2002 mean.

A visual inspection of high or low flow annual Óbidos series (Fig. 2) shows a highly intermittent signal, which justifies the preference of wavelet analysis over classical Fourier analysis (Labat *et al.*, 2000, 2001). The coefficients of the wavelet transform of a continuous-time signal $x(t)$ are defined by the linear integral operator (Grossman & Morlet, 1984):

$$C_x(a, \tau) = \int_{-\infty}^{+\infty} x(t) \psi_{a, \tau}^*(t) dt \quad \text{with} \quad \psi_{a, \tau}(t) = \frac{1}{\sqrt{a}} \psi\left(\frac{t - \tau}{a}\right) \quad (1)$$

where * corresponds to the conjugated complex. The wavelet spectrum $W_X(a, \tau)$ of a continuous-time signal $x(t)$ is defined as the modulus of its wavelet coefficients (Liu, 1994):

$$W_X(a, \tau) = C_X(a, \tau) C_X^*(a, \tau) = |C_X(a, \tau)|^2 \quad (2)$$

Fig. 2 Temporal fluctuations and corresponding Morlet wavelet analysis of the main hydrological series available on the Amazon basin at Óbidos over the period 1900–2000. Left: annual high flow ($10^3 \text{ m}^3 \text{ s}^{-1}$); right: annual low flow ($10^3 \text{ m}^3 \text{ s}^{-1}$) (adapted from Labat *et al.*, 2004).

RESULTS

El Niño–Southern Oscillation

During the 1981–2002 period, an El Niño/low discharge signal is observed in most Amazonian rivers when considering mean (Fig. 3), maximum and minimum annual discharge. The major negative anomalies are depicted in the northeastern small tributaries of the Amazon River, where the discharge is diminished by 50% during El Niño years, and also at Altamira (downstream Xingu). Significant anomalies are also observed along the Purus River and some right-hand tributaries of the Madeira River (Ji-Parana, Aripuana, and Sucunduri); the discharge in these rivers is reduced by 25% during El Niño. Elsewhere, negative anomalies during El Niño are seldom significant (Beni, Tapajós, Juruá, Branco). Along the Solimões and Negro Rivers, the main Amazon contributors, the signal is very weak. Information is still missing about the Ecuadorian and Peruvian tributaries of the Solimões River. It is noticeable that though being insignificant, there is an inverse tendency (El Niño/high discharge) in the upper Negro River (Tiquié, Uaupes) and in the Japura River, in the northwesternmost regions, especially when considering the low-flow discharge (not shown), and, on another hand, in the upper Madeira basin (Mamoré River).

The La Niña/high discharge signal is not the symmetric of the El Niño/low discharge signal; it is mainly observed in the northeastern rivers and along the Branco River, though not being always significant, and it becomes weak and insignificant along the Negro, the Solimões, the Juruá the Purus and the Beni rivers. An inverse signal with low discharge during La Niña is noteworthy in a great part of the southern Amazon basins and especially along the Mamoré and Madeira rivers0 until Fazenda Vista Alegre. This signal is very similar to that observed in the Parana River during La Niña. The same signal is also observed on low-flow waters in the upper Negro basin (not shown).

Fig. 3 Composite mean annual discharge anomalies, significant at the 90% level (circles) or not significant (triangles), during El Niño and La Niña events in the equatorial Pacific (1981–2002).

The correlation between mean discharges in the Amazon basin and ENSO indicators (SOI or SST in various regions of the equatorial Pacific) reveals that 55% of the discharge variability is explained by ENSO in the northeastern rivers; the percentage is still higher than 30% in the Branco and the downstream Negro basins, in the right hand tributaries of the Madeira and along the Purus River.

At Óbidos, on the main Amazon stem, the mean annual discharge is weak but significantly smaller (greater) during El Niño (La Niña) events during the 1981–2002 period. Consistently, the wavelet analysis of the 1903–2001 discharge series at Óbidos shows that they are characterized by 3–7 year interannual oscillations that are typical of ENSO variability (Fig. 2). Regarding low-flow discharge, the signal is nearly permanent over the 1903–2001 interval (Fig. 2, right); in contrast, the 3–7 year interannual oscillations are temporally localized in the 1900–1930 and 1980–2000 intervals when considering mean discharge (not shown) and high flow discharge (Fig. 2, left) (Labat *et al.*, 2004).

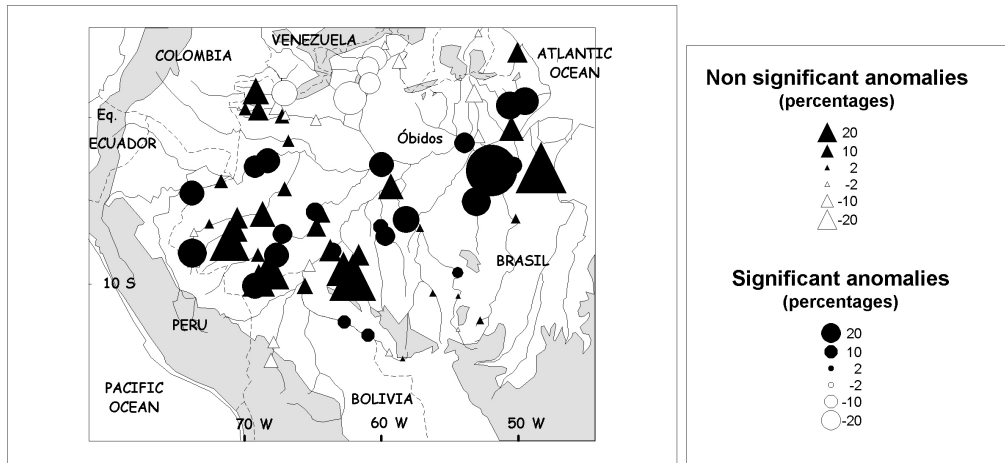

Fig. 4 Composite low flow discharge anomalies, significant at the 90% level (circles) or not significant (triangles) during cold events in the North Tropical Atlantic (period: 1981–2002, events: 1984–1985, 1985–1986 and 1993–1994).

The Northern Tropical Atlantic (NATL)

In a large portion of the Amazon basin, from the main Solimões-Amazon stem to 10°S, higher than normal low flow (Fig. 4) and mean (not shown) discharge are observed when the SST in the Northern Tropical Atlantic (NATL) is colder than usual. Depending on the stations the low-flow discharge increases by 20–40% during the cold events. An inverse relationship is highlighted along the Branco River and to a lesser extent along the Negro. Warm events in NATL (not shown) are characterized by weaker than usual discharges.

As a result the SST in NATL region explains 25–40% of the low flow discharge in the northeastern basins, in the right-hand tributaries of the Madeira River, in the Purus and downstream Juruá rivers.

At near decadal time scale (15.5 years) the wavelet analysis of the Óbidos time series also highlights variability common to low-flow discharge (Fig. 2, right) and to SST in NATL (not shown; see Labat *et al.*, 2004). This feature is particularly strong at the beginning of the 1970s when an abrupt increase in low flow discharge at Óbidos coincides with a decrease in NATL SST (Fig. 5).

Fig. 5 Low flow discharge at Óbidos and annual SST in the Northern Tropical Atlantic (5–20°N; 60–30°W). Data are standardized and an 11-year running mean is computed.

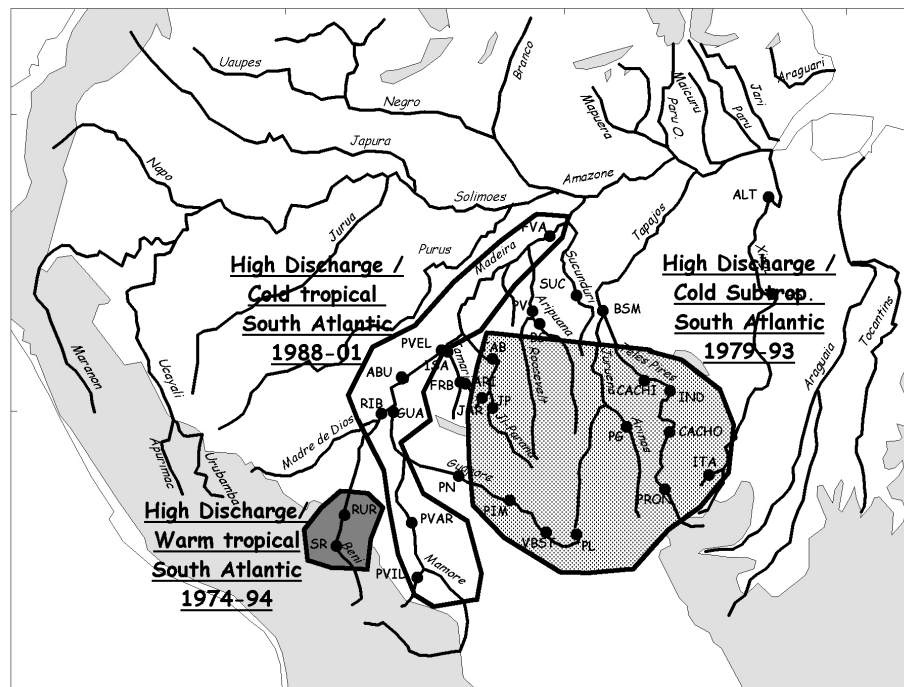

Fig. 6 Relationships between discharge and SST in the South Atlantic, tropical ($0\text{--}20^{\circ}\text{S}$; $30^{\circ}\text{W}\text{--}10^{\circ}\text{E}$) and subtropical ($20\text{--}30^{\circ}\text{S}$; $30\text{--}50^{\circ}\text{W}$). White (dark) shading indicates negative (positive) relationships between discharge in the Mamoré-Madeira (Beni) basin and the South Tropical Atlantic. Dotted shading (Upper Xingu, Tapajós and Guaporé) indicates a negative relationship between discharge and sub tropical SST (adapted from Ronchail *et al.*, 2004).

The South Atlantic (SATL)

In the southernmost regions of the Amazon basin, Ronchail *et al.* (2004) identified relationships between discharge and the South Atlantic (SATL) SST that are summarized in Fig. 6. They are generally time dependent.

In the Guaporé, upper Xingu and Tapajós, until the end of the 1980s or the early 1990s, high discharge is related to a colder than usual subtropical southern Atlantic; during the same period, in the Beni basin, high discharge is associated with a warmer than usual South Tropical Atlantic. The opposite signal is observed along the Mamoré-Madeira during the 1990s and it propagates until Fazenda Vista Alegre on the downstream Madeira.

The bi-decadal variability that is observed in high flow (Fig. 2, left) and mean discharge at Óbidos around 1970 recalls the bi-decadal variability observed in the South Atlantic (Wainer & Venegas, 2002).

CONCLUSION

A comprehensive set of data allows a detailed analysis of the relationships between discharge in the Amazon basin and SST in the tropical Pacific and Atlantic during the 1981–2002 period. Additional information is proposed to the well-known El Niño/low

discharge and La Niña/high discharge signals: the spatial extension of these signals are defined and regions with opposite El Niño/high discharge, La Niña/high discharge are identified, as well as regions without any signal. The extension of the north tropical Atlantic signal is also emphasized; in addition, it is found that this signal is significant when considering low-flow discharge values. The complexity of the relationships between discharge in the southern Amazon region and SST in the southern Atlantic were fully detailed in Ronchail *et al.* (2004).

Additional information results from the wavelet analysis of the 100-year discharge series at Óbidos, on the main Amazon stem. It is particularly important to underline the non-stationarity of the ENSO signal during the 20th century (strong at the beginning and the end of the century and weak in between) and the major changes that occurred around 1970 (Callède *et al.*, 2004), at decadal and bi-decadal time scales, possibly in connection with SST in the Atlantic.

These results are consistent with others concerning rainfall–SST relationships (Hastenrath & Heller, 1977; Aceituno, 1988; Marengo, 1992; Moron *et al.*, 1995; Liebmann & Marengo, 2001; Molinier *et al.*, 2004; Ronchail *et al.*, 2002).
